Figure 1: We present the task of 3D mirror plane prediction and depth refinement. First, we annotate several popular RGBD datasets (Matterport3D [6], ScanNet [7], NYUv2 [32]) with 3D mirror planes. Our benchmarks show that both existing RGBD dataset ‘ground truth’ raw depth data, and state-of-the-art depth estimation and depth completion methods exhibit dramatic errors on mirror surfaces. We propose an architecture for 3D mirror plane estimation that refines depth estimates and produces more reliable reconstructions (compare left and right depth and point cloud pairs from NYUv2 [32] dataset).

## Abstract

*Despite recent progress in depth sensing and 3D reconstruction, mirror surfaces are a significant source of errors. To address this problem, we create the Mirror3D dataset: a 3D mirror plane dataset based on three RGBD datasets (Matterpot3D, NYUv2 and ScanNet) containing 7,011 mirror instance masks and 3D planes. We then develop Mirror3DNet: a module that refines raw sensor depth or estimated depth to correct errors on mirror surfaces. Our key idea is to estimate the 3D mirror plane based on RGB input and surrounding depth context, and use this estimate to directly regress mirror surface depth. Our experiments show that Mirror3DNet significantly mitigates errors from a variety of input depth data, including raw sensor depth and depth estimation or completion methods.*

## 1. Introduction

Recent years have seen much progress in 3D reconstruction methods. It is now possible to acquire 3D re-

constructions of interiors with high quality geometry and texture. However, these reconstructions fail spectacularly when used in environments with mirrors and glass, both of which are prevalent in indoor spaces.

The fragility of many reconstruction methods is due to a reliance on accurate active depth sensing. Commodity sensors such as the Microsoft Kinect and Intel RealSense employ active infrared or time of flight depth sensing which requires strong signal return from sensed surfaces. Unfortunately, highly glossy and reflective surfaces such as mirrors cause either no signal return or highly unreliable depth estimates. Though it may seem that reflectors are a ‘corner case’ with few affected pixels, the resulting errors are catastrophic to reconstruction algorithms, leading to loss of camera pose tracking and geometry artifacts (see Figure 1).

Recently, Whelan et al. [35] demonstrated that by detecting mirror planes it is possible to mitigate the above issues and achieve high-quality reconstructions in scenes with many reflectors. However, their method relies on the use of an AprilTag [26] attached to a custom camera rig. The use of such custom hardware is not always feasible. In this

paper, we propose a method for identifying mirrors and estimating mirror surface depth on RGBD data collected with commodity hardware.

Our key idea is to identify mirror regions based on color information (RGB), model the mirror as a plane and use an estimated mirror normal and information from the mirror’s surroundings to predict the mirror’s position in 3D. Our work is related to the recently proposed task of mirror segmentation in 2D [20, 39]. However, we operate in 3D and focus on using 3D mirror plane estimates to improve the reliability of depth data.

To estimate the prevalence of mirrors in 3D environments and understand the severity of the above reconstruction issues, we first annotate 3D mirror planes in three popular RGBD datasets: Matterport3D [6], ScanNet [7], and NYUv2 [32]. These annotations create ‘true’ ground truth for observed mirror surfaces that was previously unavailable. We find the prominence of mirrors varies between datasets depending on their acquisition procedure, leading to a corresponding range of depth data issues and reconstruction failures. Using this data, we introduce the task of 3D mirror detection from RGB and RGBD data, and establish initial benchmark results by: i) applying state-of-the-art depth estimation and depth completion approaches to directly estimate mirror depth values; and ii) propose a simple architecture combining a MaskRCNN [14] module and a PlaneRCNN [22] module to segment mirror surfaces, estimate mirror 3D planes and refine mirror surface depth estimates. Overall, we make the following contributions:

- Introduce the task of 3D mirror plane prediction from single-view RGB and RGBD data
- Provide 3D mirror plane annotations for three RGBD datasets (Matterport3D, NYUv2 and ScanNet)
- Establish benchmarks for RGB and RGBD-based 3D mirror plane prediction, and evaluate depth completion and depth estimation approaches on the task
- Present Mirror3DNet, an architecture that predicts a 3D mirror normal and mirror segmentation to refine raw sensor depth or the output of state-of-the-art depth completion and estimation methods

## 2. Related work

We summarize related work on mirror detection, 3D plane estimation, and depth estimation and completion.

**Mirror detection and correction.** The challenges of dealing with reflective and transparent surfaces in 3D reconstruction and robotics have long been recognized. Yang and Wang [38] proposed a sensor fusion technique for dealing with LiDAR sensor failures on mirror and glass surfaces. Käshammer and Nüchter [16] detect mirrors and correct laser-scanned point clouds based on heuristics using known mirror dimensions. The general problem of mirror surface

reconstruction is addressed by work on reflectometry. Early work focuses on the stereo image setting [2], active illumination hardware setups [3], or single image input but relying on detecting reflection correspondences of reference target objects [23]. In recent years, there has been renewed interest in identifying mirrors, glass, and transparent objects for improved reconstruction [35] and for manipulation in robotics [34]. Whelan et al. [35] rely on observing the reflection of an AprilTag [26] attached to a custom scanner. Work on mirror detection for uncontrolled RGB images using deep learning is less explored, with a few recent works. Yang et al. [39] introduce a network and dataset for identifying mirrors in 2D images, and Lin et al. [20] extend the earlier work by extracting mirror context features to improve mirror detection. In contrast, we study 3D mirror plane estimation in RGBD datasets without relying on custom hardware or other assumptions on the capture setup.

**3D plane detection and plane reconstruction.** There is recent work on detecting 3D planes from single-view images using neural networks [21, 22, 37, 41]. Unlike this work, our focus is not on creating a planar segmentation of the entire observed scene. We focus specifically on identifying mirror regions and corresponding 3D planes. Identifying mirrors in RGB images is challenging, as mirrors contain a reflection of the environment which can be difficult to distinguish from non-reflected regions. Mirror detection remains challenging even with RGBD data as mirror depth values tend to be noisy and unreliable.

**Depth estimation and depth completion.** Depth estimation and completion are recently popular tasks. Typically, the term depth estimation is used when the input is only color (RGB) and has no depth information. The term depth completion is used when the input is RGBD, where the D (depth) channel is noisy and may have missing values. Existing methods for single-view depth estimation [1, 4, 9, 10, 18, 19, 24, 29, 30, 40] and depth completion [15, 25, 27, 31, 42] improve depth prediction for the entire image, relying on reconstructed 3D mesh data that is assumed to provide accurate depth. Chabra et al. [5] show that an exclusion mask for noisy areas such as reflective surfaces can result in better reconstruction. We leverage 3D mirror plane estimates to improve the accuracy of existing depth estimation and completion methods. Moreover, we note that both depth estimation and completion methods are typically evaluated on ground truth data that does not account for noise due to mirrors and glass. Widely employed datasets such as NYUv2[32], Matterport3D[6, 42], ScanNet [7], and SUN3D [12, 36] have noisy or missing depth for reflectors (see Figure 1). Thus, these regions are typically ignored or evaluated with incorrect values as the ground truth. We contribute ground truth 3D mirror annotations for three RGBD datasets, allowing for correct benchmarking of mirror surface depth estimation and completion.

Figure 2: Our human-in-the-loop mirror mask and 3D plane annotation workflow. We leverage an iteratively trained mirror image classifier to assist a user in rapidly selecting all mirror images in an input image dataset. The images are then annotated with mirror surface polygon masks. The masks and their corresponding depth images are used to initialize mirror plane estimates with a RANSAC approach. The user then refines and verifies all 3D mirror plane estimates.

### 3. Mirror3D dataset

To enable benchmarking of 3D mirror plane prediction and surface depth estimation, we create Mirror3D: the first large-scale dataset of mirror annotations for RGBD images. We design a human-in-the-loop workflow that enables efficient iterative annotation of mirror masks and mirror 3D planes. Using this workflow, we annotate RGBD images containing mirrors in three common RGBD datasets (NYUv2 [32], Matterport3D [6], and ScanNet [7]) to create an aggregated dataset that contains 7,011 annotated 3D mirror planes in 5,894 RGBD frames.

#### 3.1. Dataset construction

Our annotation workflow consists of three stages: i) mirror image classification, ii) mirror mask annotation, and iii) mirror plane annotation. Figure 2 shows the overall pipeline. We first pretrain a ResNet-50 classifier on a seed dataset of ‘mirror present’ and ‘no mirror present’ RGB images from Structured3D [43] (roughly half of the images contained mirrors, approximately 7,000 images total). We then sort all input RGBD dataset candidate frames by using the mirror classification score. An annotator confirms whether images contain a mirror, splitting them into ‘mirror’ and ‘no mirror’ sets in batches of 100 images. As this verification proceeds through each batch, the classifier is finetuned on the dataset of newly annotated ‘mirror’ and ‘no mirror’ images to improve the efficacy of the classification score sorting whenever less than 20 additional mirror images are added from a single 100-image batch. The annotator was instructed to stop looking for additional mirror images when less than 5% of a batch contains mirrors. This first stage was performed by one annotator and took approximately 28 hours in total over 8 batch iterations.

In the second stage, we used the CVAT<sup>1</sup> annotation interface to define mirror mask polygons for all mirror images. The annotators specified two types of mirror mask polygons: a ‘coarse’ mask and a ‘precise’ mask. The coarse

<sup>1</sup>[github.com/openvinotoolkit/cvat](https://github.com/openvinotoolkit/cvat)

	Matterport3D	ScanNet	NYUv2	Total
mirror planes	4,662	2,218	131	7,011
RGBD images	3,782	1,987	125	5,894
RGBD panoramas	2,468	–	–	2,468
3D scenes	79	282	96	457

Table 1: Summary statistics for our Mirror3D dataset.

mask ignores occluding objects and small mirror protrusions, while the precise mask is a pixel-accurate boundary of the visible mirror surface in each image. This stage was performed by four annotators over approximately 67 hours.

The last stage used a 3D interface developed with Open3D [44] that allows inspection of an initial 3D mirror plane normal estimate obtained by filtering mirror mask border depth values using RANSAC [11]. The annotators could check that the plane is correct, refine the 3D plane estimate by specifying three plane points on the point cloud and manually adjusting, or indicate that it is impossible to define a plane (in cases where the point cloud is extremely noisy). After the 3D planes are annotated, we generated turntable videos of the point clouds with the annotated planes from a frontal and top-down view to allow for quick verification. Planes identified as incorrect were further adjusted and corrected. This last stage took a total of approximately 50 hours of annotation effort by the same expert annotator who carried out the first stage.

In total, the annotators inspected approximately 30,000 RGBD images to obtain the final 7,011 3D mirror plane annotations. The mirror image classification stage took 3s per image on average. The mirror mask annotation stage took 25s and 57s per mirror instance for coarse mask and precise mask respectively. Finally, the mirror plane annotation stage takes 20s per mirror instance on average.

#### 3.2. Dataset statistics

At the end of our annotation, we end up with a total of 7,011 mirror 3D plane and instance mask annotations

across RGBD images from all three source datasets. Table 1 shows a more detailed breakdown of dataset statistics. We split this data following the standard training, validation and test splits of each source dataset. We note that mirrors are found in roughly 22.9% of Matterport3D panoramas (from a total of 79 out of 90 Matterport3D residences) and 96 of 464 (20%) NYUv2 scenes, which are relatively high fractions compared to only 282 out of approximately 1,500 ScanNet scenes (18.8%). We hypothesize that this is due to the capture setup and methodology employed by the ScanNet authors who may have avoided scanning scene regions that contain mirrors. Appendix A provides additional analysis of the annotated data in terms of mirror region location, prominence and distribution across the images.

#### 4. Mirror3DNet: refining mirror depth

Having constructed our dataset of 3D mirror plane annotations, we would now like to address the task of predicting 3D mirrors from a single-view RGB or RGB-D image, and using these predictions to improve estimated depth values on mirror surfaces. Because mirrors are often planar, we make the simplifying assumption that we can model a mirror using a mirror mask and a mirror plane. We will show that we can improve depth estimation from RGB-only image input or depth completion results from an RGBD image using the predicted 3D region and plane. Thus, the input to our approach is either an RGB image or an RGBD image with missing or incorrect depth for mirrors. The output is an estimated 3D mirror plane and an RGBD image with refined depth for the mirror.

Our goal is not to propose a new approach for depth estimation or depth completion, but rather to benchmark state-of-the-art approaches for both and demonstrate that we can leverage a simple mirror-aware architecture to improve depth output for both families of approaches. To do this, we propose the Mirror3DNet architecture (see Figure 3). This architecture uses a Mask R-CNN [14] module and a 3D mirror plane estimation module inspired by PlaneRCNN [22] to predict mirror masks and planes respectively. A depth estimation or completion module may be used first to predict depth values given an input RGB or RGBD image, and then Mirror3DNet is applied to predict the mirror mask and mirror plane. We evaluate this architecture’s performance on depth prediction as well as mirror mask prediction and mirror normal estimation.

Thus, the overall architecture consists of three modules: mirror mask segmentation, mirror plane estimation, and depth estimation or completion. PlaneRCNN uses a warping loss to enforce consistency of reconstructed 3D planes from nearby viewpoints. Our problem setting only assumes a single image input, so we replace the warping loss module with a mirror plane estimation module which refines the depth on the mirror region.

#### 4.1. Mirror mask and plane prediction

In this part of the architecture, we address detection and segmentation of the mirror surface. To do this, we employ a mirror classification (MC) branch and a mirror bounding box regression (MR) branch, as well as an instance segmentation (Seg) branch, all based on the Mask R-CNN module. We also add an anchor normal classification (AC) branch and an anchor normal regression (AR) branch after the ROI pooling layer to predict the mirror plane normal.

Since it is challenging to directly regress the mirror normal values, these latter two branches follow an approach similar to PlaneRCNN and decompose the regression into a classification phase and a residual prediction phase. In the classification phase we obtain a coarse orientation of the mirror normal by classifying into one of a few anchor normal orientations using the AC branch. We use 10 mirror anchor normals from a k-means clustering of all mirror normals in the annotated Matterport3D training set. During training, the module predicts one anchor normal for each positive proposal. For supervision, we assign each mirror instance to its closest mirror anchor normal.

Given the anchor normal classification we then regress the residual using the AR branch to form the final normal vector. The final normal  $n$  is the sum of the anchor normal and the normal residual. The ground truth mirror residual of an instance is the distance vector between ground truth mirror and the ground truth mirror anchor normal.

#### 4.2. Depth estimation and completion

As Figure 3 shows, our network architecture accommodates a depth estimation or completion module. The details of this part depend on the input type. That is, whether we take an RGB image or RGBD data including noisy depth. If the input is an RGB image, we first use a depth estimation module to produce an initial depth map estimate. Then the rest of the Mirror3D architecture refines the depth map into  $D_{pred}$ . If the input is an RGBD image with a noisy depth map  $D_{noisy}$ , we directly carry it forward for refinement through the architecture.

To estimate the 3D mirror plane we need to combine the mirror mask and mirror normal estimates from the previous stage with a depth offset  $d$  for the plane. Since depth values on the mirror surface itself are missing or unreliable, we rely on mirror border regions which are often non-reflective materials and significantly more reliable. Thus, we compute the average depth of points that fall on pixels within a small offset of the mirror mask border. Given the predicted mirror segmentation mask, we create a mirror border mask region by expanding outwards by 25 pixels. This threshold corresponds to roughly 5% of average image dimensions and we have empirically found it to be reasonable. We then take the average depth of all points in this mirror mask as the offset of the mirror plane  $d$ .

Figure 3: Overall diagram showing how the Mirror3DNet architecture can be used for either an RGB image or an RGBD image input. For an RGB input, we refine the depth of the predicted depth map  $D_{\text{pred}}$  output by a depth estimation module. For RGBD input, we refine a noisy input depth  $D_{\text{noisy}}$ . The Mirror3DNet module predicts a mirror normal  $n$  and mirror mask. Then, by computing an offset depth  $d$  based on depth values at the mirror border, we can determine the position and orientation of the 3D mirror plane, and produce refined output depth values that improve mirror surface depth accuracy.

The Mirror3DNet module is trained under three types of loss terms: i) mirror segmentation loss, ii) mirror anchor normal classification loss, and iii) mirror anchor normal regression loss. In mirror segmentation, we use a cross-entropy loss for mirror classification and mirror mask prediction. We use a smooth L1 loss for mirror bounding box regression, and a cross-entropy loss for mirror anchor normal classification. For mirror anchor normal regression, we use a smooth L1 loss. The total loss  $\mathcal{L}$  is then:

$$\mathcal{L} = \text{CE}(a_i, a_i^*) + \text{Smooth}_{L1}(r_i, r_i^*) + \text{CE}(c_i, c_i^*) + \text{Smooth}_{L1}(b_i, b_i^*) + \text{CE}(m_i, m_i^*)$$

where  $a_i$  and  $a_i^*$  are the predicted and ground truth mirror anchor normal class,  $r_i$  and  $r_i^*$  are the  $1 \times 3$  predicted mirror regression vector and ground truth mirror regression vector,  $c_i$  and  $c_i^*$  are the predicted mirror proposal class and ground truth proposal class,  $b_i$  and  $b_i^*$  are the predicted and ground truth mirror bounding box parameter,  $m_i$  and  $m_i^*$  are the predicted and ground truth mirror mask.

### 4.3. Implementation details

We implement our network architecture in PyTorch [28]. We used the Adam [17] optimizer with initial learning rate set to  $10^{-4}$ ,  $\beta_1 = 0.9$  and  $\beta_2 = 0.999$  and without weight decay. The ResNet-50 [13] backbone was initialized with weights pretrained on ImageNet [8]. We train our model for 50,000 iteration with batch size 32. For NYUv2 data, we crop the original image by 2.5% on each side to remove

the white border and resize to  $480 \times 640$ . We resize Matterport3D data to  $512 \times 640$ . For depth estimation and depth refinement experiments on Matterport3D, we train with all Matterport3D train set depth data and fine-tune on Matterport3D mirror data.

## 5. Experiments

### 5.1. Datasets

We carry out our evaluation on the NYUv2 and Matterport3D datasets, following their train/val/test splits. To show the importance of accurate mirror depth we evaluate against both original ‘raw depth’ ground truth depth and our annotated mirror depth, computed using the ‘precise’ masks. We use the following depth data in our experiments:

**NYUv2-raw:** the 1449 annotated RGBD frames from NYUv2 (795 frames in train and 654 frames in test), captured with a Kinect depth sensor and exhibiting noise and missing data on mirror surfaces.

**NYUv2-ref:** the corrected version of NYUv2-raw, with mirror surface depth computed using our 3D mirror plane annotations.

**MP3D-mesh:** depth rendered from the Matterport3D reconstructed mesh, as used by Zhang and Funkhouser [42].

**MP3D-mesh-ref:** the corrected version of the above using our 3D mirror plane annotations.

## 5.2. Evaluation metrics

**Depth estimation and completion.** We report several standard metrics for depth estimation and completion [9, 29, 42]: root mean squared error (RMSE), scale-invariant root mean squared error (s-RMSE), mean absolute value of the relative error (AbsRel), structural similarity index measure (SSIM), and  $\delta_i$ . RMSE is commonly used to measure disparity error, but since depth estimation methods are often limited by the size-distance ambiguity in predicting depth values, we compute s-RMSE [9] which assumes the optimal scale is available. Following Huang et al. [15], we also report SSIM [33], which measures the perceptual similarity of large-scale structures between images. The  $\delta_i$  metric denotes the percentage of predicted pixels where the relative error is less than a threshold  $i$ . Specifically,  $i$  is chosen to be equal to 1.05, 1.10, 1.25, 1.25<sup>2</sup> and 1.25<sup>3</sup>. Here, the larger  $i$  is, the more sensitive the  $\delta_i$  metric. Larger values of  $\delta_i$  reflect a more accurate prediction. We find the metrics to be largely correlated and report the RMSE and SSIM in the main paper, and provide complete results in Appendix D. Following standard practice [42], we only evaluate on pixels with ground truth depths  $> 0.00001$  as depth of 0 often indicates no depth reading.

**RMSE:**  $\sqrt{1/|P| \sum_{p \in P} \|D^*(p) - D(p)\|^2}$  where  $D(p)$  and  $D^*(p)$  is depth and ground truth depth at point  $p$ .

**s-RMSE:**  $\sqrt{1/|P| \sum_{p \in P} \|D^*(p) - sD(p)\|^2}$  where  $s$  is the least square root of  $1/n \sum (D^* - sD)^2$ .

**AbsRel:**  $1/|P| \sum_{p \in P} |D^*(p) - D(p)| / D^*(p)$ .

**SSIM:**  $\frac{(2\mu_{D^*(p)}\mu_{D(p)} + c_1)(2\sigma_{D^*(p)D(p)} + c_2)}{(\mu_{D^*(p)}^2 + \mu_{D(p)}^2 + c_1)(\sigma_{D^*(p)}^2 + \sigma_{D(p)}^2 + c_2)}$  where  $c_1 = 0.0001$ ,  $c_2 = 0.0009$  as in Huang et al. [15].

**$\delta_i$ :** percentage of pixels within error range  $i$ , where the error range is defined by  $\max(D^*(p)/D(p), D(p)/D^*(p)) < i$ .

All the above metrics are reported separately for depth points within the ground truth mirror region, points outside the mirror, and together for all depth points in each frame.

**Mirror mask prediction and plane estimation.** We adopt the commonly used mean average precision (mAP) to evaluate mirror mask segmentation predictions (**Seg-AP**). We also extend the mAP to take into account whether the angle error is below 30° (**30°-AP**).

**Seg-AP:** segmentation AP, with IoU threshold starting from 0.50 to 0.95 at 0.05 steps. The final AP score is the average over the 10 threshold steps.

**30°-AP:** 30 degree AP, with the same IoU threshold setting as Seg-AP and an angle error threshold of 30 degrees. Angle error is the angle between predicted mirror normal and ground truth mirror normal.

Input	Train Depth	Method	Seg-AP $\uparrow$	30°-AP $\uparrow$
RGB	*	Mirror3DNet	<b>0.464</b>	<b>0.256</b>
RGBD	mesh	Mirror3DNet	0.416	0.255
RGBD	mesh-ref	Mirror3DNet	0.419	0.217
RGBD	mesh	PlaneRCNN [22]	0.319	0.190
RGBD	mesh-ref	PlaneRCNN [22]	0.334	0.220

Table 2: Evaluation of mirror mask segmentation and mirror normal prediction on Matterport3D validation set. We observe that our Mirror3DNet module improves on mask segmentation, and normal estimation metrics.

## 5.3. Qualitative evaluation

Figure 4 shows two qualitative comparison examples. We include more qualitative examples in Appendix C. The top set of visualizations shows the improvements on NYUv2-raw and NYUv2-ref data using our Mirror3DNet module to enhance results from several depth estimation and depth completion approaches. We note that outlier depth points behind the mirror surface are significantly reduced after using Mirror3DNet (see depth RMSE images and top-down point cloud visualizations). The improvements are consistent across input depth approach, whether RGB-based depth estimation is employed or RGBD-based depth completion is employed. The bottom set of visualizations shows comparisons on the MP3D-mesh and MP3D-mesh-ref datasets. This data exhibits fewer depth outliers due to the input being rendered from a 3D reconstructed mesh that incorporates manual mirror region correction. Despite this, the Mirror3DNet module still improves depth accuracy on the mirror surface, in particular for RGB-based depth estimation approaches.

## 5.4. Quantitative evaluation

**Mirror 3D plane prediction.** We first quantify the improvements introduced by our Mirror3DNet architecture over a baseline PlaneRCNN module for predicting the mirror 3D plane. Table 2 reports overall quantitative metrics for the Matterport3D dataset. We see that the Mirror3DNet module leads to improved mirror mask segmentation and plane normal estimates. The simplest Mirror3DNet module (without depth estimation module) gets the highest Seg-AP and 30°-AP. We select a mirror anchor normal count of 10 and a mirror border width of 25 pixels based on results from ablation experiments (see Appendix B).

**Mirror depth refinement.** We conducted a series of experiments on the NYUv2 and Matterport3D test sets to quantify the improvements in depth value prediction offered by our Mirror3DNet architecture, and summarize overall trends. Please refer to Appendix D for additional results and metrics. We used three different datasets as the ground truth for the purposes of the evaluation reported here: NYUv2-

Figure 4: Visualizations of depth frames, depth errors against ground truth (RMSE mapped to colormap), and resulting 3D point clouds (PC) for NYUv2 (top) and Matterport3D (bottom). We compare the output depth from state-of-the-art RGB-based depth estimation approaches (bts [18], vnl [40]) and an RGB-based depth completion approach (saic [31]). We contrast the outputs from these approaches when trained directly on the corrected datasets which leverage our 3D mirror plane annotations (NYUv2-ref and MP3D-mesh-ref), against output of the approaches when trained on the uncorrected original datasets (NYUv2-raw and MP3D-mesh-raw), and against outputs after refinement using our Mirror3DNet module. Overall, we observe that mirror depth errors are significantly reduced after applying Mirror3DNet, as seen by the reduced RMSE error in mirror regions, and the reduced prominence of depth outlier points.

ref, NYUv2-raw, and MP3D-mesh-ref. Results with the first dataset (NYUv2-ref) treated as the ground truth are in Table 3. These results show how far from the ‘correct ground truth’ the various depth estimation and prediction methods are, and how much of an improvement Mirror3DNet can provide. We note that methods trained on the corrected NYUv2-ref depth have significantly better performance on mirror area depth prediction. The Mirror3DNet module trained on Matterport3D can generalize to NYUv2 and helps improve depth accuracy for mirrors significantly

when applied to methods trained on NYUv2-raw, which would be the practical input at capture time.

We contrast the above set of results against the results reported in Table 4, where the ground truth is assumed to be the original, uncorrected NYUv2-raw dataset. We make the observation that evaluating on raw depth as ground truth gives a different (and inaccurate) ranking of methods compared to the corrected ground truth in NYUv2-ref. Not surprisingly, the ranking on NYUv2-raw gives an edge to the methods that were trained on the raw depth. This is

Table 5: Depth prediction evaluation on MP3D-mesh-ref test set, for images containing mirrors.

however, a misleading result, as the ‘assumed to be correct ground truth’ is highly inaccurate for mirror regions.

Lastly, in Table 5 we see results using the MP3D-mesh-ref dataset as the ground truth. The overall trends remain the same, but we note that on this data there are less pronounced differences in performance (i.e. it is still better to train on refined depth). We hypothesize that this is due to mesh cleanup and post-processing relying on human-provided annotation of some reflective and transparent surfaces. In other words, the Matterport reconstruction pipeline that was used to produce the mesh from which MP3D-mesh data is rendered already incorporates a degree of mirror surface correction. While this annotation is not explicitly specified

by the Matterport3D dataset, the mesh reconstruction itself makes use of it, and the rendered mesh depth will thus have cleaner depth than without human intervention. Our goal with Mirror3DNet is to automate this depth refinement so that human intervention is not required at capture time or mesh reconstruction post-processing.

## 5.5. Limitations and future work

Our mirror depth refinement approach is a simple first step but it is subject to several limitations that suggest future work directions. We assume planar mirrors and use a fixed border width to estimate the mirror depth offset. Both assumptions can be addressed using more advanced mirror detection approaches. Moreover, in this paper we only focused on using 3D mirror plane estimates to refine depth values at the mirror surface. Observations of reflected objects in mirrors can be leveraged to further improve reconstruction of other surfaces beyond the mirror. The estimated 3D mirror planes can also be used to create more realistic rendered visuals from 3D reconstructions, by simulating reflections and light propagation from the mirror surfaces.

## 6. Conclusion

In this paper, we tackled the problem of 3D mirror plane prediction and mirror depth refinement. We created Mirror3D: a large-scale dataset of 3D mirror plane annotations based on three popular RGBD datasets which we use to obtain corrected ground truth depth on mirror surfaces. Using this data, we develop Mirror3DNet: a mirror depth refinement architecture that can be used to refine depth estimation or depth completion output. Our experiments show that mirror depth errors in popular RGBD datasets are prevalent, and that treating existing depth data as ground truth can misrepresent depth prediction method performance. Moreover, we show that our Mirror3DNet architecture helps to improve mirror depth estimates from depth estimation and depth completion approaches, significantly mitigating 3D reconstruction artifacts due to mirror surfaces.

**Acknowledgements.** Many thanks to Yiming Zhang for help in developing annotation verification and visualization tools, and the dataset website. We also thank Hanxiao Jiang, Yongsen Mao and Yiming Zhang for their help with dataset annotation. We thank Shitao Tang for helpful early conversations on the Mirror3DNet neural architecture used in our work. We are grateful to the anonymous reviewers for their helpful suggestions. Table 6: Breakdown of number of mirror planes, RGBD images, panoramas, and 3D scenes across splits for Mirror3D.

## A. Mirror3D Dataset Statistics

Here, we provide additional summary statistics for the Mirror3D dataset that we constructed based on RGBD frames from NYUv2 [32], Matterport3D [6], and ScanNet [7]. We also provide several examples of annotated 3D mirror planes to illustrate the diversity of scenarios in which they occur.

**Train/test/val split.** Table 6 provides the detailed breakdown by number of planes, images, panoramas, and scenes across train/val/test for the Mirror3D dataset. Note that NYUv2 does not have a validation split.

**Mirror in-frame location distribution.** Figure 5 plots the distribution of mirror mask centroids within the image plane per source RGBD dataset and also overall for the entirety of Mirror3D. Overall, mirror centroid points tend to cluster around the upper part of the image. This is expected as mirrors are usually placed at human eye level. We do note clear differences in the distributions for different datasets, which combine to form an overall distribution with fairly dense coverage of the image frame.

**Mirror depth distribution.** The distance from the camera of the mirror surface is an important characteristic influencing the reliability of the surrounding depth points, and correspondingly the challenge of performing depth estimation or completion on images including mirrors. Figure 6 plots histograms of the maximum mirror depth value for each mirror instance in our dataset, again broken down by source RGBD dataset and overall. We show histograms for both the raw original depth values and the corrected depth values after annotation of the 3D mirror planes. We note that the corrected depth value distributions are tighter, with fewer outliers at larger depth values. This indicates that the annotation mitigates many of the ‘floating depth noise’ artifacts in the raw data.

**Mirror normal distribution.** In Figure 7 we plot the distribution of mirror 3D plane normal direction relative to the camera viewing direction. Most mirror normals are clustered around facing the camera center and have relatively small angle deviations from that orientation. There are again interesting differences between the source dataset distributions that we attribute to the use of tripod-based equip-

ment with fixed tilt angles (Matterport3D) vs the use of handheld scanning sensors (NYUv2 and ScanNet).

**Mirror pixel ratio distribution.** We define the *mirror ratio* as the fraction of image pixels that belong to a mirror instance. In Figure 8, we plot the mirror ratio distribution across source RGBD datasets, and for the overall Mirror3D dataset. We note that there is a relatively broad range of mirror ratios, though few images have ratios higher than 0.5. This is understandable, as that would correspond to scenarios where the mirror takes up most of the image and would thus show the equipment or the operator.

**Coarse vs precise masks.** During our annotation process, we annotate both a ‘coarse’ and a ‘precise’ mask for each mirror plane (see Figure 9). The ‘coarse’ mask serves as an indication of the entire mirror surface (including occluded areas), while the ‘precise’ mask provides a pixel-accurate boundary of the visible mirror surface in each image.

**Example annotations.** In Figures 10 to 12 we provide several examples of mirror mask and 3D mirror plane annotations from our Mirror3D dataset across the three source RGBD datasets. We show image pairs, with one image showing the mirror masks on the RGB frame, and the other visualizing the 3D mirror plane and depth points ‘behind’ the mirror plane in each point cloud. Mirrors occur in a variety of scenarios, and the outlier depth points cause many ‘floating artifacts’ that our mirror plane annotations allow us to mitigate.

Figure 5: Distribution of mirror mask centroids in image plane, plotted by source RGBD dataset (a through c) and overall (d). Each point corresponds to a mirror instance mask. Matterport3D is collected using a static tripod-based sensor and exhibits strong vertical centering of the mirror centroid point. In contrast, ScanNet and NYUv2 were collected with hand-held depth sensors which were frequently held in a slightly downwards facing angle, and avoided capturing mirrors ‘head on’. The overall dataset therefore exhibits a somewhat bimodal distribution of mirror centroid along the vertical axis.

Figure 6: Distribution of the maximum depth value per frame by source RGBD dataset (a through c) and overall (d) for both the raw and refined depth in images with mirrors. After correcting the noisy depth values using our 3D mirror plane annotations, the maximum depth is consistently reduced for all datasets showing the reduction of depth outlier points at far distances (usually associated with ‘floating points’ behind mirror surfaces).

Figure 7: Distribution of mirror normals by source RGBD dataset (a through c) and overall (d). Each point corresponds to the normal of a 3D mirror plane instance. The overall distribution reveals that many normals are at angles that are close to ‘facing towards’ the camera with small horizontal deviations. We note interesting differences between the distributions for different source datasets. The Matterport3D frames exhibit a tight horizontal vertical angle distribution, which we hypothesize is due to the tripod-based sensor. This is in contrast to both NYUv2 and ScanNet which were both captured with handheld devices and exhibit broader distributions.

Figure 8: Distribution of the ratio of mirror pixels to total pixels, by source RGBD dataset (a through c) and overall (d).

Figure 9: Example of 'coarse' and 'precise' masks in our Mirror3D dataset, images from the Matterport3D [6] dataset. The 'precise' mask provides a pixel-accurate boundary of the visible mirror surface in each image.

Figure 10: Example 3D mirror plane annotations in our Mirror3D dataset. Source RGBD data from the NYUv2 [32] dataset. In each image pair, the mirror mask is shown as a transparent red on the RGB image, the mirror plane is in light blue on the point cloud, and erroneous depth points that are incorrectly behind the mirror plane in the raw depth are shaded in orange.

Figure 11: Example 3D mirror plane annotations in our Mirror3D dataset. Source RGBD data from the Matterport3D [6] dataset. In each image pair, the mirror mask is shown as a transparent polygon (with different color signifying each mirror instance) on the RGB image, the mirror plane is in light blue on the point cloud, and erroneous depth points that are incorrectly behind the mirror plane in the raw depth are shaded in orange.

Figure 12: Example 3D mirror plane annotations in our Mirror3D dataset. Source RGBD data from the ScanNet [7] dataset. In each image pair, the mirror mask is shown as a transparent polygon (with different color signifying each mirror instance) on the RGB image, the mirror plane is in light blue on the point cloud, and erroneous depth points that are incorrectly behind the mirror plane in the raw depth are shaded in orange.

# anchors	Seg-AP $\uparrow$	30°-AP $\uparrow$
3	0.396	0.253
5	0.419	0.228
7	0.434	0.224
10	<b>0.464</b>	<b>0.256</b>
12	0.386	0.199

Table 7: Ablation on anchor normal count. We evaluate a spectrum of anchor normal counts in terms of mirror normal estimation. Using 10 anchor normals gives the highest segmentation AP and 30 degree AP.

## B. Ablations

We present ablations for two aspects of our approach: the choice of mirror anchor normal count and the mirror border threshold. For our ablation studies, we train our model on Matterport3D train set and evaluate on the validation set.

**Impact of anchor normal count.** We evaluate performance on a spectrum of anchor normal counts (i.e. different values of  $k$  for the  $k$ -means clustering that we use to select anchor normals in the training set). Table 7 shows that using 10 anchor normals achieves the best performance on both mirror segmentation and mirror normal estimation metrics on the MP3D-mesh (Matterport3D mesh-based depth) dataset.

**Impact of mirror border width.** We experiment with different mirror border width values for estimating the mirror plane offset on the MP3D-mesh-ref dataset. Table 8 summarizes the results. The mirror border width has a relatively small impact on the accuracy of the estimated depth, with a mirror border width of 25 pixels giving the best results.

## C. Additional qualitative results

We provide more qualitative results presented in a similar layout as the qualitative results figure in the main paper. Figure 13 shows two qualitative comparison results from NYUv2 (top two sets) and six from Matterport3D (bottom six sets). Note that by using Mirror3DNet to refine depth

Border width	RMSE $\downarrow$			SSIM $\uparrow$		
	Mirror	Other	All	Mirror	Other	All
15	0.851	<b>0.798</b>	<b>0.858</b>	0.823	<b>0.798</b>	<b>0.791</b>
25	<b>0.839</b>	0.800	<b>0.858</b>	<b>0.825</b>	<b>0.798</b>	<b>0.791</b>
35	0.842	0.801	0.859	<b>0.825</b>	<b>0.798</b>	0.784

Table 8: Ablations on mirror border width. We tested performance on three difference border widths (number of pixels expanded outwards from mirror mask region) on the MP3D-mesh-ref dataset. We find that a border width of 25 produces the lowest RMSE on mirror regions.

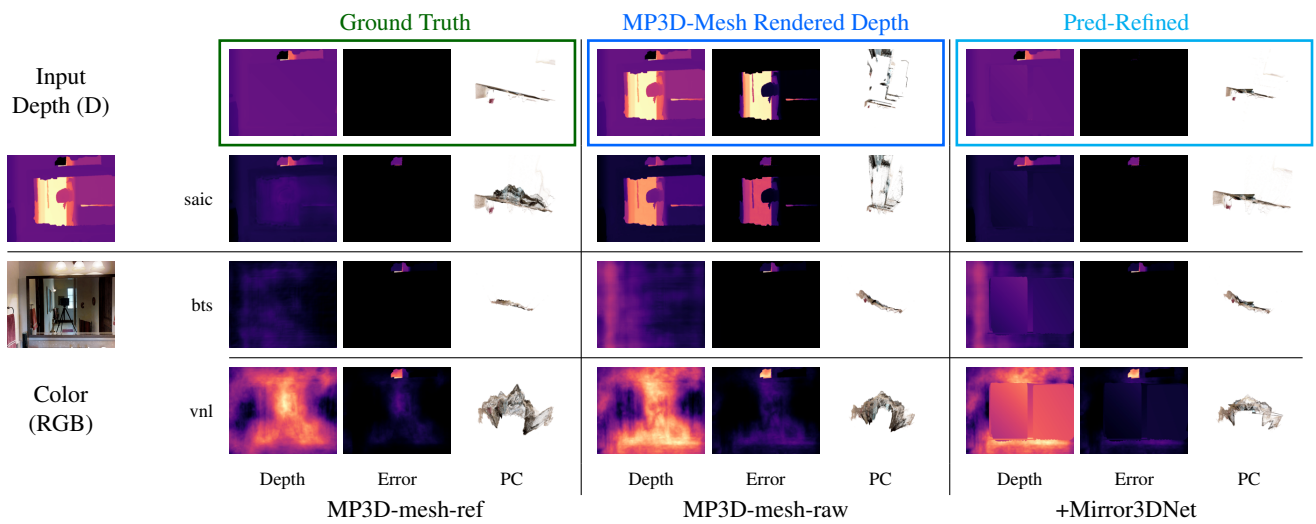

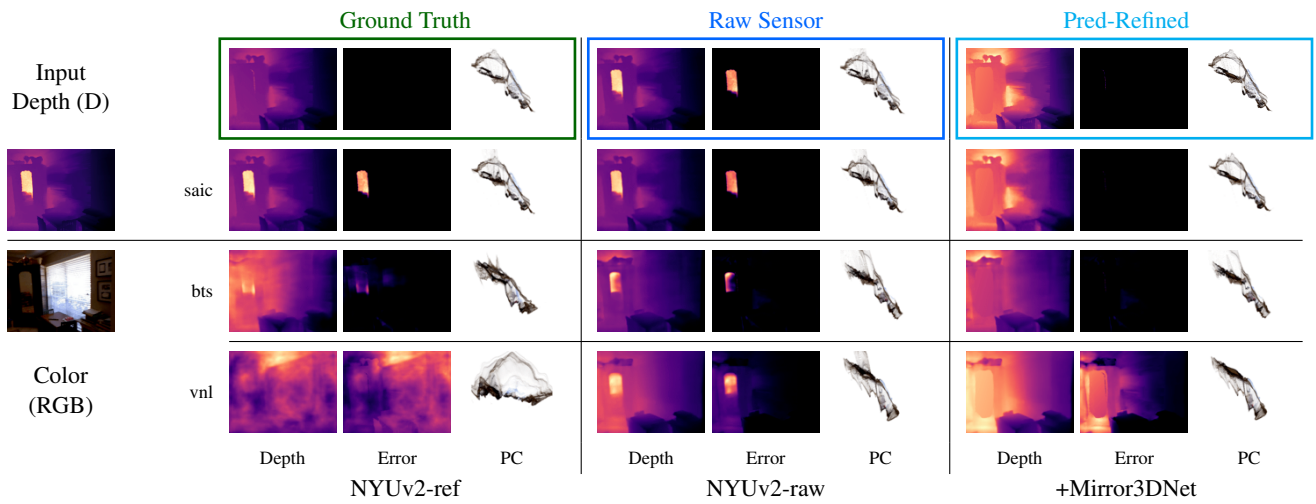

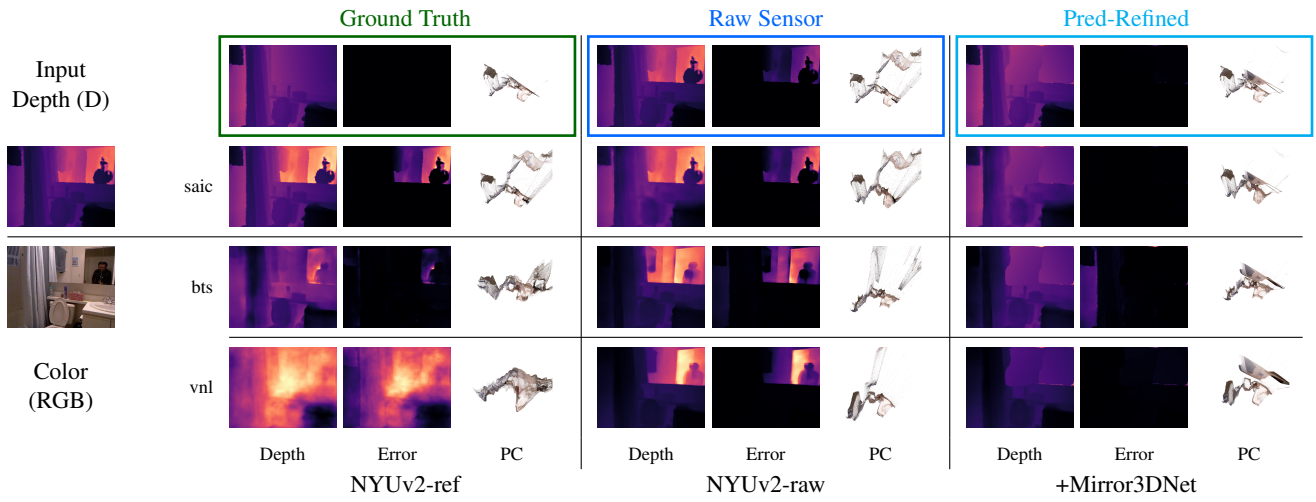

output from various depth estimation and completion approaches we can significantly reduce the depth error against the corrected ground truth depth (lower error values, particularly in mirror regions shown in the rightmost RMSE visualization column).

We also provide qualitative examples of predicted mirror segmentations for NYUv2 (Figure 14) and Matterport3D (Figure 15). We train Mirror3DNet and PlaneRCNN on the Matterport3D train split, and evaluate on NYUv2 and Matterport3D test splits. We note that Mirror3DNet trained on just RGB, no depth (first column) provides better detection of mirrors than when trained with depth (other columns). Due to the noisy nature of the depth values around mirror regions, depth is not a reliable signal for the presence of a mirror for both Mirror3DNet and PlaneRCNN.

## D. Additional quantitative results

Since pixels with depth value  $< 0.00001$  are filtered out during evaluation, we provide statistics analyzing what percentage of pixels are filtered (Table 9). For NYUv2, there are no pixels that are filtered. In contrast, we see that a large fraction of mirror pixels are invalid for raw sensor depth from Matterport3D and ScanNet. For depth derived from the Matterport3D mesh reconstruction, there are fewer mirror depth values that are filtered out during evaluation. Overall, the percent of pixels that are filtered out during evaluation is low.

We also compile a complete set of result tables including all the quantitative evaluation metrics we defined in the main paper. We train separate models for NYUv2 and Matterport. For each dataset, models are trained on the train split and evaluated on the test split. We train all models three times with different random seeds and report the average and the standard error across the three runs. In Table 10 we report the full set of metrics for experiments using the NYUv2-ref dataset. Contrast these results with the ones obtained when using the NYUv2-raw dataset, shown in Table 11 to see the impact of using the original raw depth as the ground truth for evaluation. Similarly, in Table 12 we report complete metrics for the experiments using MP3D-mesh-ref, and contrast these metrics against the original dataset depth being used as ground truth in Table 13.

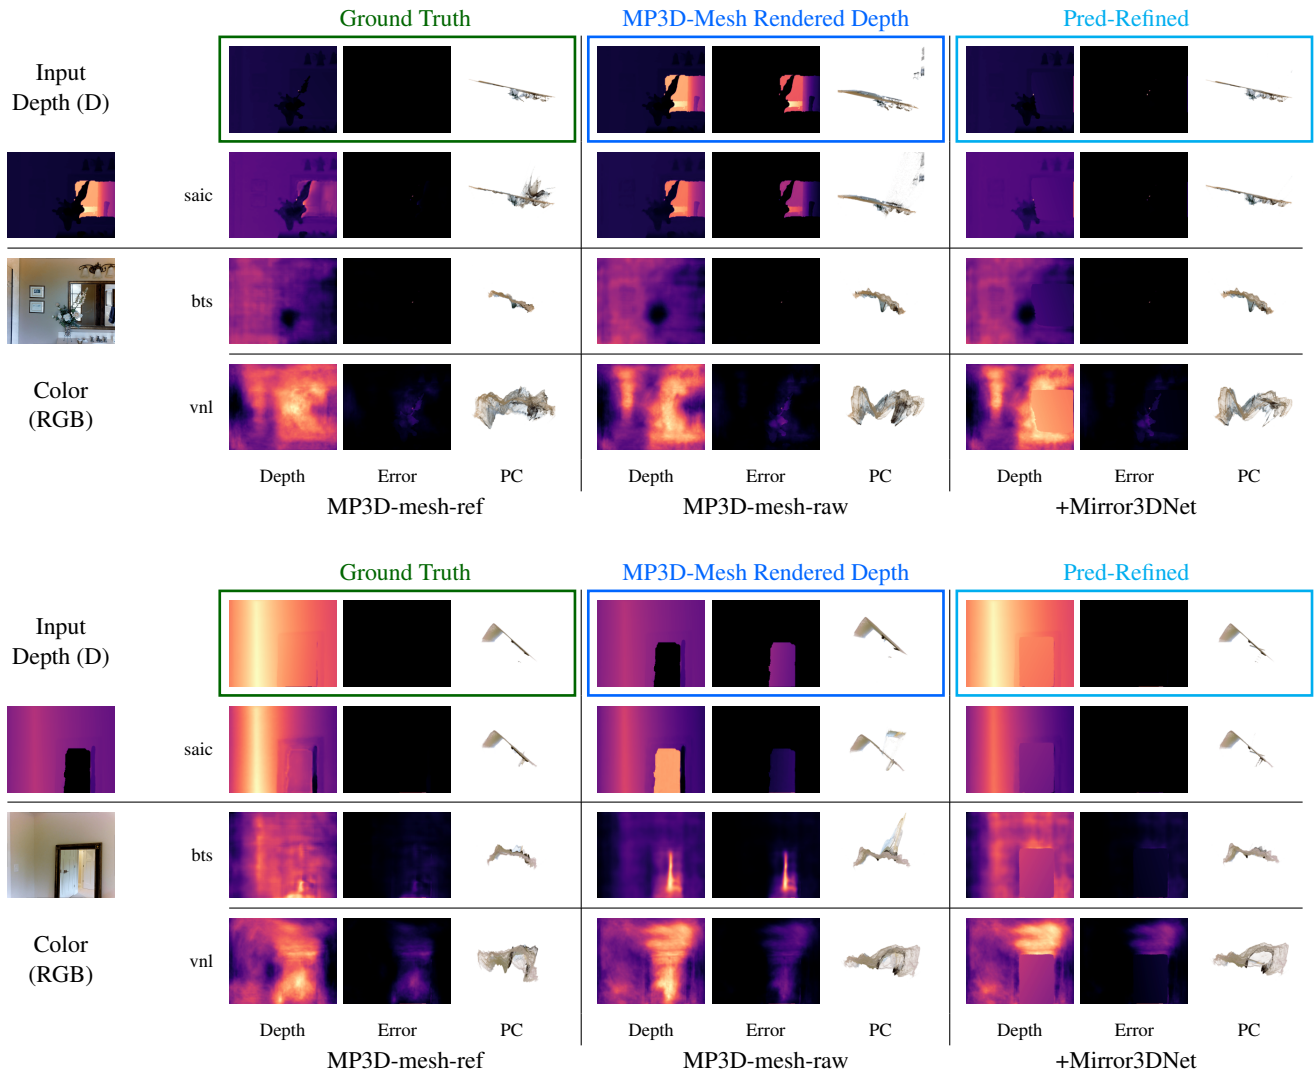

Figure 13: Additional qualitative results. The top two samples are results from NYUv2 [32], the bottom six samples are from Matterport3D [6].

Figure 14: Mirror segmentation results for NYUv2. Models were trained on Matterport3D mirror data. We see that Mirror3DNet trained on Matterport3D generalizes to NYUv2 mirror data and gives the best segmentation results. The predicted mirror mask is shown as a transparent polygon with a confidence score on the left top corner in each image.

Figure 15: Mirror segmentation results for Matterport3D. Overall, we see that Mirror3DNet gives the best results.

	Matterport3D-sensor				Matterport3D-mesh				ScanNet-sensor			
	Train	Val	Test	All	Train	Val	Test	All	Train	Val	Test	All
% mirror pixels over frames	39.89	34.00	40.31	40.10	6.00	5.93	6.75	6.34	30.04	32.20	33.74	31.89
% mirror pixels over mirror pixels	29.05	20.68	28.20	24.87	4.75	2.51	3.48	3.58	24.34	26.00	26.69	25.52
% pixels over all pixels	3.96	2.90	4.51	4.24	0.65	0.35	0.56	0.52	2.94	3.18	2.30	3.06

Table 9: Breakdown of percent of pixels with original depth values  $< 0.00001$  across train/val/test splits for Matterport3D and ScanNet. NYUv2-sensor does not have any pixels with depth value  $< 0.00001$ . Note that during evaluation (on val/test), these pixels are filtered out. We see that a large fraction of mirror pixels are invalid for raw sensor depth from Matterport3D and ScanNet. For depth derived from Matterport3D mesh reconstruction, there are fewer mirror pixel values that are filtered out during evaluation. Overall, the percent of pixels that are filtered out during evaluation is low. After refining the depth for mirrors, our Mirror3D dataset does not contain any depth value  $< 0.00001$  and so all pixels are included in the evaluation.
